

**THE WESTERN UNION CENTRAL TELEGRAPH OFFICE AND PLANT IN NEW YORK CITY.**

On July 18, 1890, the upper stories of the main building of the Western Union Telegraph Company, in this city, were destroyed by fire. The experiences of such disasters have shown that water is one of the greatest enemies to switch boards and general telegraph plant. The new portions of the Western Union building replacing the portions destroyed have now been practically finished, the operating room is in full operation, and to-day it is the second largest telegraph office in the world, and possesses a plant protected, as far as possible, not only from fire, but also from water. We illustrate more particularly the operating room and electric current generating plant.

Two thousand one hundred and fifty wires at present enter the building through underground conduits. The wires are bunched in cables of 100 conductor each, and are received by a slate terminal board, carried in an iron frame, with the capacity of nearly 1,100 more wires than it at present accommodates. This board is situated in the basement of the main building. The cables are carried thence each through a separate three inch pipe, by way of two fire-proof shafts, up to the main operating floor, where they are distributed wire by wire.

The floor is of the ordinary fire-proof type, consisting of H-iron floor beams, with brick arches between them. Upon the floor, after being leveled up, wooden moulds were laid and concrete was then run in to surround them. The wooden moulds were of shape and length to produce a series of gutters running over the floor in different directions, according to the plan of the operating tables and switch boards. After the concrete had hardened, the moulds were removed, leaving open ducts or channels traversing the room in all directions. The channels are covered by slabs of slate, 13 inches wide and 1 inch thick, which can be removed for the introduction or removal of wires or for repairs or alterations. The rest of the floor was brought up to the level of the slate by rock asphalt, leaving all level and true.

The ducts thus made are from three to five inches deep and ten inches wide. The intersections come under the center of the operators' tables. At each intersection a 13 inch square hand plate is placed that can readily be removed for reaching the wires. Even from the tables to the floor where the wires rise to the relays and sounders they are protected by being cased in split iron pipes.

Our general view of the main operating room shows the distribution of the operators' tables and, to that extent, illustrates the general plan of the ducts. The wire is copper of Nos. 16 and 18 B. W. gauge. All joints are soldered and insulated with the same care as is bestowed upon a cable, a special detail of the company's cable crew having been appointed for this work.

The current is generated by dynamos which are distributed in three groups each of five machines placed in series for the regular work, while for local and special service six other dynamos of 6 volts, 23 volts and

series, so that the terminals from the different machines which are led to the plug disks which regulate the distribution to the switch boards rise in potential for each one. The potentials are named from their numbers the first, second, third, fourth, and fifth potential respectively. The field for the entire group of dynamos is supplied by the fifth machine. All the fields are

SWITCH BOARD CONNECTIONS.

connected in parallel, and for each field a resistance box is intercalated for individual adjustment of its field. The right hand group in the cut is a reserve group, designed to replace either of the others when they have to be suspended from operation. It is to be observed that the two left hand groups deliver the current in opposite directions, some wires being supplied with current of one direction and others with that of another. Hence, the right hand group designed to replace either of the others has to have arrangements for reversing its polarity. This is effected by reversing the terminal connections of the fifth machine. This necessarily causes this machine to deliver its current in the opposite direction, but, as the fields of the other four machines

two dynamos being of 70 volts each and the others of 60 volts each. The special dynamos are plugged in as required by special plug switches, shown on the left of the main group.

The current thus generated is received at the switch boards, which are seen in the drawing Fig 3, on the left of the main operating room, and one of which is also shown in Fig. 4 of the drawing and in the special view on this page. For ordinary purposes, the first three potentials only are used, the fourth and fifth being for quadruplex and similar work. As the current comes from the dynamos, it is received by four leads or horizontal bus wire seen at the top of the switch board. The lower one represents a 70 volt potential, the next two represent 140 volts each, and the other one 200 volts potential. From the bus wires leads descend to the disks of the switch board. For each potential, a special lamp is used, through which the current has to go before reaching the disks, and which introduces resistance. In operation the filaments of these lamps glow with a dull red. Should any abnormal current, due to grounding, go through the line, the lamp immediately burns brightly, showing trouble upon the line in question. This brightening of lamps is always watched for. A special type of lamp is used containing one filament, two filaments in series, and three filaments in series respectively, according to the resistance desired. At the dull red glow, they carry  $\frac{1}{10}$  of an ampere current. By plugs, the disks and bars of this switch board can be connected in the most varied ways, in order to bring about almost any connections. From each vertical bar a wire runs to the lines, and in the course of this wire two spring jacks are placed. Each of these spring jacks can accommodate four wedges. By introducing a wedge with two metal faces and an ebonite center, it will be seen that a loop can be put into the line. The switches are so constructed that four of these loops can thus be introduced, each one in series, so that each line can have eight loops all in series connected with it. Thus, by proper connections, it will be seen that there is hardly any limit to the combinations which can be brought about. A single loop leading to a relay is represented in the drawing.

In the cut of the switch board connections will be noticed a safety fuse, shown of about the natural size above. These are known as "W. B. G." protectors. They consist of a short piece of No. 20 fuse wire. Around its end, No. 30 silk-covered German silver is wound a number of times. The current has to go through the German silver wires. Any abnormal current will heat the German silver wire and this heat is relied on to melt the fusible wire. Three-quarters of an ampere is the maximum current that the protector will carry.

In the cut, Fig. 4, the general appearance of the

WESTERN UNION TELEGRAPH PLANT, NEW YORK—DYNAMO CONNECTIONS.

45 volts difference of potential are provided. These dynamos replace all batteries. At present there is not a single cell in operation in the building. Before the fire there were 10,000 cells in use.

In our illustration of the dynamos and of their connections, the three groups of five dynamos are indicated by being numbered from 1 to 5. They are connected in

are supplied by the current from the fifth one, and as this current is reversed, the current in these machines is, by the same action, reversed, on account of the change of polarity of their fields.

By means of the disks and plugs the dynamos are plugged in or out as desired. On the same drawing are indicated the different potentials for each wire, the first

back of the switch board is shown in perspective with the bank of lamps appearing above the disks. An interesting feature is the one represented in this cut. The backs of the switch boards are closed in with glass doors and walls, so as to have the greatest amount of light possible shed upon them. A large hatchet switch is placed on the wall, by which they can all be cut off

in case of any accident. This cutting out is to prevent any injurious effects from short-circuiting, in the case of fire in the building, when the switch board, being wet by water from the fire engines, might give occasion to this trouble were the current turned on.

The general operations of the office are facilitated by the use of the cash carrier railroad and by pneumatic tubes. An elevated gallery occupies approximately the center of the main operating room. An extensive system of cable cash carriers, embracing 16 radiating lines, with four to six stations on each line, connects with all parts of the room. By this the messages are distributed from and returned to the central gallery. The cash carrier runs at the rate of about 750 feet a minute, enabling the most distant part of the room to be reached in 10 seconds. Twenty-four pneumatic house tubes terminate in this gallery; and four street pneumatic tubes running north to 23d Street, and intermediate offices, and four running south to exchanges below Wall Street, are also operated from this gallery. All messages coming in or going out from the main operating room must go through this central gallery.

Fig. 2 of the drawings shows the time repeater. At noon, every week day, the time is transmitted from the United States Naval Observatory at Washington. This signal has to be sent out over many lines in all directions; at present 60 different lines transmit it. The time repeater includes 92 repeating magnets. These are operated on a local circuit, which in its turn is governed by a relay connected to the Washington circuit. The repeating points of the 92 magnets are connected by loops to the main line switches. This apparatus represents a multiplication of relays, and can be used for sending 92 repetitions of one message over 92 different lines by a single operator, and it is contemplated on election nights and similar occasions to thus use it.

The average business done in this office is over 100,000 messages per day. The longest circuit is that extending from New York to San Francisco, about 3,400 miles long. Of the 750 lines leaving the building, the greater part are operated by the Morse system, the majority of the operators' desks seen in the engraving being devoted to this system. Besides this there are four Wheatstone, 42 duplex and 92 quadruplex lines, and two lines occupied by combination printing instruments. The office accommodates about 800 operators. Our thanks are due to Mr. Alfred S. Brown, Electrical Engineer of the Western Union Telegraph Co., for courtesies received.

**Improvement in Stokehold Ventilation.**

By the system of Mr. W. H. Martin the usual unsightly ventilating cowls on deck are done away with, the necessary down draught being obtained by the utilization of the heat radiated from the main boilers and uptakes. This lighter air is allowed to rise up through an enormous space between an inner and outer funnel, causing a powerful down current of fresh air through the stokehold combing, at the same time thoroughly preventing the rising of any smoke or dust to the deck, as is usual when cleaning fires and quenching ashes. To insure the fresh air reaching the stokehold floor, there is a light air-tight screen or bulkhead built in front of each end of the boilers, reaching from the deck right down to within 6 feet from the stokers' floor, the lower part being on hinges to allow access to the smoke box doors. As the whole of the air drawn off by the annular funnel space, to which is to be added that needed for combustion in the furnaces, has to pass down in front of these air screens, the result is a powerful draught of fresh air at all times, independent of the direction or force of the wind on deck, keeping the stokehold at a temperature considerably lower than in the sunshine on deck, and but from 5° to 15° Fah. above that in the shade. This system, which is much more economical than the fan, is in use on most Dutch steamers trading to the East Indies, and has proved to be of great value.

Four electric fans have been placed by the Crocker Wheeler Company in the turrets of the powerful iron vessel Miantonomoh, the intention being that they shall blow away the smoke from the guns.

**AN EXPERIMENT IN ACOUSTICS.**

BY GEO. M. HOPKINS.

In the annexed engraving is shown a very simple and effective method of indicating visibly the vibrations of a reed, tuning fork or diaphragm. It is not assumed that it can replace any of the existing methods of rendering visible indications of sonorous

VIBRATIONS SHOWN BY SMOKE RINGS.

vibrations, but it adds another very pretty acoustic experiment to the list of those already known.

In Fig. 1 are shown two forms of apparatus which yield practically the same results. In one a reed is clamped in a vise at one end and provided at the other end with slip of wood attached firmly by a wrapping of thread. To the wooden slip is glued an ordinary paper pill box, having a diameter of about two inches and a depth of 3/4 inch to 1 inch. In the bottom of the box is made a 1 inch hole in which is secured the

end of a paper tube 1 inch in diameter and about 1 inch long. The cover of the box is perforated with a 1/4 inch round hole. If the material of the cover is coarse and thick, a larger hole is made and over it is glued a piece of fine thin Bristol board, which is perforated with a 1/4 inch round hole.

In the box thus mounted is placed a strip of blotting paper bent into V-shape and rendered non-absorbent at the bend by means of melted wax paraffin or something of a similar nature. One end of the blotting paper is moistened with hydrochloric acid and the other with aqua ammonia. The particles of ammonium chloride which form by the combination of the vapors of ammonia and hydrochloric acid are so minute as to float in the air like particles of smoke.

When the reed is vibrated, a minute vortex ring is formed at each excursion of the box and thrown off in the manner illustrated. A reed having a low rate of vibration (say 32 or less per second) is required, and the amplitude of vibration must be small.

When the box is attached to a tuning fork, the action is prolonged. It is, of course, necessary to compensate for the box on one limb of the fork by a weight on the other.

In Fig. 2 is shown a cylindrical box considerably larger than those already described. It is divided into two compartments by a thin rubber diaphragm, and closed at the front, with the exception of a 1/4 inch round aperture. Blotting paper, charged with hydrochloric acid and ammonia, is placed between the diaphragm and the apertured front, and sounds are uttered in the short tubes projecting from the box. The vibration of the diaphragm causes puffs of air to issue from the small aperture at the front of the box, carrying the fumes of ammonium chloride, which render the vortex rings visible. The sounds uttered are necessarily of very low pitch. If the vibrations are too frequent in any of the forms of this experiment, the rings merge into each other and the effect is lost. In the apparatus shown in Fig. 2, a mere flutter of the tongue or lips gives good results.

It is obvious that a burning substance capable of yielding a good volume of smoke will answer quite as well as the ammonium chloride.

**DISTINGUISHED ELECTRICIANS.**

The portraits here presented represent men who, while they have achieved notability in the electric world, have, in so doing, shown that they possessed the requisites for success in any branch of work. Untiring industry, great ingenuity, and a belief in themselves would have made them great in any of the executive departments of life. Thomas Alva Edison's story has been told so often that it cannot but be a trite one. He was born on the 11th of February, 1847, at Milan, Ohio. He began life at the age of twelve as a train boy, soon advancing to be a news dealer with four young assistants. He then began practicing telegraphy, and at last obtained a position in Port Huron. He soon began to invent, and in 1864 he moved to Memphis and had one of his inventions, an automatic repeater, put into service. He struggled along, inventing, working at his profession, and experimenting, until he went to Boston in 1868, where he was able to open a workshop for developing his inventions. Shortly afterward he was retained by the Western Union Telegraph Company, and started an electrical laboratory at Newark, where he employed 300 men. In 1876 he moved to Menlo Park, New Jersey, and in 1887 left Menlo Park and erected in Orange, New Jersey, what is supposed to be the largest experimental laboratory of its kind in the world. His inventions, which are numbered by hundreds, center largely on electricity, although one of the most wonderful of his achievements, the phonograph, is not an electrical invention at all.

Alexander Graham Bell was born in Edinburgh, Scotland, March 3, 1847, being therefore almost exactly the same age as Edison. His father and grandfather were both language teachers, and the young Bell's attention was directed to language by the course of studies prescribed by his father. The synthesis of artificial speech, by Helmholtz's method, is said to have early engaged his attention, and he resolved to pursue one of the outcomes of his studies, multiple telegraphy,
